Submitted 17 April 2015. Accepted 7 September 2015.

Plants and animals rely on immune receptors, known as nucleotide-binding domain and leucine-rich repeat (NLR)-containing proteins, to defend against invading pathogens and activate immune responses. How NLR receptors respond to pathogens is inadequately understood. We previously reported single-residue mutations that expand the response of the potato immune receptor R3a to AVR3a, a stealthy effector from the late blight oomycete pathogen Phytophthora infestans. I2, another NLR that mediates resistance to the wilt-causing fungus Fusarium oxysporum f. sp. lycopersici, is the tomato ortholog of R3a. We transferred previously identified R3a mutations to I2 to assess the degree to which the resulting I2 mutants have an altered response. We discovered that wild-type I2 protein responds weakly to AVR3a. One mutant in the N-terminal coiled-coil domain, I2I141N, appeared sensitized and displayed markedly increased response to AVR3a. Remarkably, I2I141N conferred partial resistance to P. infestans. Further, I2I141N has an expanded response spectrum to F. oxysporum f. sp. lycopersici effectors compared with the wild-type I2 protein. Our results suggest that synthetic immune receptors can be engineered to confer resistance to phylogenetically divergent pathogens and indicate that knowledge gathered for one NLR could be exploited to improve NLR from other plant species.

Plant diseases are one of the main threats to modern human life, and the need for sustainable crop disease resistance is becoming increasingly urgent (Fisher et al. 2012; Pennisi 2010). Plants have evolved various disease resistance mechanisms to defend against pathogens. Sustainable crop improvement based on these mechanisms often involve resistance (R) genes: plant loci that encode immune receptors (Cook 2000; Jones et al. 2014; Michelmore et al. 2013). One challenge is to engineer plants with broad-spectrum disease resistance (i.e., that can defend against a wide spectrum of pathogens). Although this can be achieved by pyramiding multiple immune receptors with different pathogen resistance spectra, single R genes that function against multiple pathogens do occur. One example is the tomato gene Mi-1.2, which confers resistance to pathogens from different phyla: arthropods (aphids and whiteflies) and a nematode (Atamian et al. 2012; Nombela et al. 2003). Cf-2, an extracellular tomato immune receptor, also mediates resistance to both the fungus Cladosporium fulvum and the root-parasitic nematode Globodera rostochiensis (Lozano-Torres et al. 2012). Moreover, in Arabidopsis, RPS4 and RRS1 mediate resistance to the bacteria Pseudomonas syringae andRalstonia solanacearum but also to the fungus Colletotrichum higginsianum (Birker et al. 2009; Deslandes et al. 2003; Gassmann et al. 1999; Narusaka et al. 2009). However, pathogens continuously evolve new races that overcome immunoreceptor-specific mediated disease resistance. The challenge for plant breeders and biotechnologists is to generate new resistance gene specificities rapidly enough to keep up with pathogen evolution. Engineering synthetic wide-spectrum immune receptors that target more than one pathogen is one approach to rapidly deliver agronomically useful resistance genes.

Plants resist pathogenic invasion through cell surface and intracellular immune receptors that recognize pathogen-secreted molecules and activate immune responses (Dodds and Rathjen 2010; Win et al. 2012). The largest family of intracellular immune receptors is the nucleotide-binding (NB) leucine-rich repeat (LRR) (or NLR) protein family, an important element of peptidoglycan-recognition (PR) protein family, an important element of defense against pathogens in both plants and animals (Jacob et al. 2013; Maekawa et al. 2011b). In plants, NLR proteins recognize effectors: pathogen-secreted molecules that normally modulate host cell processes to the benefit of the pathogen (Bozkurt et al. 2012; Dodds and Rathjen 2010; Hogenhout et al. 2009; Win et al. 2012). NLR tend to recognize one or a limited number of effectors, resulting in NLR-triggered immunity or effector-triggered immunity (Dodds and Rathjen 2010; Jones and Dangl 2006; van Ooijen et al. 2007; Win et al. 2012). There are two major classes of NLR proteins, depending on their N terminal domains:
coiled-coil (CC)-NB-LRR (or CNL) proteins, with a predicted CC structure, and Toll/interleukin-1 receptor (TIR)-NB-LRR (or TNL) proteins, with a TIR domain (Andolfi et al. 2014; Pan et al. 2000). The NB domain, also known as NB-ARC (shared by the mammalian protein Apaf-1, plant resistance proteins, and the nematode Caenorhabditis elegans Ced-4 protein), is the most conserved among the NLR proteins and is thought to act as a switch between the resting (ADP-bound) and activated (ATP-bound) state of the receptor (Maekawa et al. 2011b; Takken and Goverse 2012; Takken et al. 2006; Tameling et al. 2006). The C-terminal LRR domain tends to be more polymorphic, with the number and length of the LRR being highly variable between different NLR proteins (Takken and Goverse 2012). Activation of NLR receptors usually results in a localized cell death response known as the hypersensitive response (HR), which is associated with restricting pathogen colonization of the host tissue (Spoel and Dong 2012; Win et al. 2012).

The CNL class of NLR has dramatically expanded in the Solanaceae (nightshade) botanical family (Andolfi et al. 2014). In tomato, for example, 18 distinct clades of CNL genes are present in every chromosome, whereas only a single TNL clade occurs (Andolfi et al. 2014). Two agronomically important genes occur in the Solanaceae CNL-8 clade. 

\[ R_3a \]

from the wild potato Solanum demissum confers resistance to specific strains of the late blight oomycete pathogen Phytophthora infestans that carry the avirulence effector AVR3aEM (Armstrong et al. 2005; Bos et al. 2006). In tomato, the 

\[ R_3a \]

ortholog I2 confers resistance against race 2 of the ascomycete fungus Fusarium oxysporum f. sp. lycopersici, the agent of tomato wilt disease (Ori et al. 1997; Simons et al. 1998; Takken and Rep 2010). F. oxysporum f. sp. lycopersici secretes the effector AVR2, which activates I2-mediated immunity. Single-amino-acid mutations of AVR2 in race 3 of the pathogen abolish recognition by I2 and overcome I2-mediated disease resistance (Houterman et al. 2009; Takken and Rep 2010). A current challenge is to breed \( R \) genes that respond to the stealthy AVR2 variants.

\[ S. \ demissum \ R_3a \]

is one of the first late blight \( R \) genes to be bred in cultivated potato (Gebhardt and Valkonen 2001; Hawkes 1990; Huang et al. 2005). The \( R_3a \) immune receptor strongly responds to the P. infestans RXLR-type host-translocated AVR3aK80/I103 effector (referred to as AVR3aKI) but weakly to AVR3aEMO/I103 (AVR3aEM), which differs in only two amino acids in the mature protein (Armstrong et al. 2005; Bos et al. 2006). P. infestans strains that carry AVR3aKI, either in a homozygous or heterozygous configuration, are avirulent on \( R_3a \) potatoes (Armstrong et al. 2005; Bos et al. 2006, 2009; Chapman et al. 2014; Segretin et al. 2014). P. infestans strains homozygous for AVR3aEM are virulent on \( R_3a \) and have increased in frequency in P. infestans populations since the 19th century, to become dominant in many potato-growing regions of the world (Chowdappa et al. 2013; Cooke et al. 2012; Li et al. 2013b; Yoshida et al. 2013, 2014). This prompted Segretin et al. (2014) to expand the response spectrum of R3a to AVR3aEM, and also to explore the possibility that transferring previously identified R3a variants to I2 could expand the response spectrum of I2 to AVR3aEM and confer partial resistance to P. infestans strains carrying either of the AVR3a variants. In addition, I2I141N responded to two stealthy F. oxysporum f. sp. lycopersici AVR2 effector variants that evade response by the wild-type I2 receptor. This work demonstrates that synthetic NLR receptors can confer expanded pathogen effector and disease resistance spectra, and that knowledge of one NLR can be exploited to improve homologous NLR from other plant species.

### RESULTS

I2 responds weakly to AVR3aKI.

Given that I2 and \( R_3a \) are orthologous genes, we first determined whether I2 responds to the two AVR3a variants from P. infestans. We co-expressed I2 with each of the AVR3a isoforms using Agrobacterium tumefaciens-mediated transient transformation (agroinfiltration) in the model plant Nicotiana benthamiana and scored for hypersensitive cell death phenotypes. We found that I2 responds weakly to AVR3aKI (HR index typically between 0.5 and 1.2 on a scale of 0 to 3 at 6 days postinfiltration [dpi]) (Fig. 1; Supplementary Fig. S1). Occasionally, I2 showed a weak response to AVR3aEM (HR index less than 0.5) (Fig. 1). Both AVR3a variants were expressed alone in N. benthamiana to exclude any possibility of weak autoactivity of these constructs (Supplementary Fig. S2). No cell death reaction was seen upon transient expression of either AVR3a variant, suggesting that the I2/AVR3a cell death is specific. These findings, together with the high amino-acid sequence similarity between \( R_3a \) and I2, prompted us to test the possibility that transferring previously identified R3a+ mutations to I2 expands the response profile of this NLR receptor.

Homology models of the NB-ARC domain highlights conserved R3a+ residues.

Although the overall similarity between \( R_3a \) and I2 is relatively high (83% amino-acid similarity), the NB-ARC domain displays the highest sequence conservation (Huang et al. 2005) (Fig. 2A). We generated structural models of the conserved CC and NB-ARC domains using four online prediction programs (IntFOLD2, iTASSER, Phyre2, and SWISS-MODEL).

For the CC domain, three of the prediction programs (iTASSER, Phyre2, and SWISS-MODEL) identified the CC domain of the barley CNL protein MLA10 as the top-scoring template for modeling of the I2 CC-domain. Interestingly, IntFOLD2 (Buenavista et al. 2012; McGuffin et al. 2015) produced a model based on the CC domain of the potato CNL protein Rx (Fig. 2B), which adopts a distinct structure, quite different at the three-dimensional level from MLA10. Despite these different models (either of which could be valid), in each of the structures, the I2 I141 residue is consistently positioned to the C-terminus of the defined CC units and, therefore, is
predicted to be located at an interdomain region between the CC and NB-ARC domains (Supplementary Fig. S3).

For the NB-ARC domain, the structures of the equivalent regions of Apaf-1 (Vaughn et al. 1999), DARK (Pang et al. 2015), and CED-4 (Yan et al. 2005) were consistently used as templates by the programs for modeling, with high confidence scores. We choose to use the models based on Apaf-1, because the crystal structure of this template has been determined to the highest resolution and the residues forming the ATPase active site are appropriately positioned. As would be predicted from the modeling of the R3a NB-ARC domain (Segretin et al. 2014), the I2 N330 position maps to the junction of the NB and ARC1 regions (Fig. 2B), near the NB site and adjacent regions that have been implicated in nucleotide exchange events in plant NB-LRR proteins and associated with activity (van Ooijen et al. 2008).

The structural models indicate that the two gain-of-function positions in the I2 CC and NB-ARC domain occur in interdomain regions, and mutations at these positions may affect the overall conformational dynamics of the protein. Therefore, we proceeded with the generation of I2 mutants in these positions.

The I2<sup>1141F</sup> and I2<sup>N330Y</sup> mutants are nonfunctional and autoactive, respectively.

We generated mutants of I2 that are equivalent to R3a<sup>1148F</sup> and R3a<sup>N336Y</sup>, the R3a+ mutations in the CC and NB-ARC domains. We assayed these I2 mutants, I2<sup>1141F</sup> and I2<sup>N330Y</sup>, with AVR3a<sup>KI</sup> and AVR3a<sup>EM</sup> using agroinfiltration in N. benthamiana. I2<sup>1141F</sup> showed a loss-of-response because it did not trigger any cell death when co-expressed with either one of the AVR3a isoforms (Fig. 3). I2<sup>N330Y</sup> was autoactive; it triggered strong cell death (HR index 3) even in the absence of effector proteins (Fig. 3). These results indicate that the specific R3a+ amino-acid substitutions do not confer desirable phenotypes to I2 but highlight the importance of these two positions for I2 activity.

**I2 mutants at positions 141 and 330.**

We hypothesized that additional amino-acid substitutions at I2 positions 141 and 330 might yield an expanded response to AVR3a. To test this, we randomly mutagenized I2 codons 141 and 330 (Fig. 4). Next, we cloned mutagenized I2 molecules in the binary vector pk7WG2 (Karimi et al. 2002) under the transcriptional control of the Cauliflower mosaic virus 35S promoter, and transformed them into A. tumefaciens. We obtained mutants representing all different amino acids for position 330, whereas we generated a library with only 12 amino acids for position 141. We screened the mutant clones by co-expression with the AVR3a isoforms in N. benthamiana and grouped the cell death phenotypes in four categories: strongly autoactive (HR index = 3 in the absence of effectors), loss-of-response (no HR phenotype), similar profile to wild-type I2, and gain-of-response (expanded response to AVR3a<sup>EM</sup>). Substitutions of the Asn in position 330 with Cys, His, Leu, Tyr, Arg, Thr, Ser, Val, Trp, Phe, Met, and Ile resulted in autoactive mutants; Glu,

### Fig. 2.

I2 and R3a are highly similar in the N-terminal region. **A**, Protein sequence alignment of the CC and NB-ARC domains of I2 and R3a. The amino-acid positions that were subjected to mutation are highlighted in yellow. Conserved R-protein motifs in the NB-ARC domain are overlaid according to van Ooijen et al. (2007). Blue lines delimit the three subdomains of the NB-ARC: NB, ARC1, and ARC2. **B**, Structural model of the CC and NB-ARC domain of I2. Models were generated by remote homology modeling using the INTFold2 server (Buenavista et al. 2012; McGuffin et al. 2015). The CC domain is shown in pink, and NB-ARC is shown in three different colors depending on the subdomain: NB (green), ARC1 (purple), and ARC2 (blue). Amino acids corresponding to the single-residue I2 mutations are shown in yellow stick representation. Carbon atoms of ATP are shown in white. Locations of NLR-protein motifs are indicated with arrows.

Pro, and Asp gave a loss-of-response phenotype; and Lys, Gln, and Ala had a response profile similar to the wild-type I2 (Fig. 4). Substitution of the Ile in position 141 with Tyr resulted in an autoactive mutant; Arg, Pro, Val, Ala, Lys, Leu, Thr, and Asp showed a loss-of-response phenotype. Interestingly, I2\textsuperscript{H141N}, which carries a substitution of Ile to Asn in position 141, responded more strongly to AVR3\textsubscript{EM} compared with the wild-type I2 (Fig. 5).

**A single amino-acid change expands the response of I2 to AVR3\textsubscript{EM}.**

To determine the extent to which the single-site I141N mutation in the CC domain of I2 expands its response profile to the AVR3\textsubscript{EM} variant, we co-expressed I2\textsuperscript{H141N} with both AVR3a isoforms using *N. benthamiana* agroinfiltration. I2\textsuperscript{H141N} responded to AVR3\textsubscript{EM} (HR index between 2.5 and 3 on a scale of 0 to 3), and also exhibited a stronger response to AVR3\textsubscript{K1} when compared with wild-type I2 (HR index approximately 2 versus 0.7 for the wild type) (Fig. 5). I2\textsuperscript{H141N} also exhibited a weak response in the absence of effector (HR index approximately 1), which is lower than the response to the two AVR3a variants. These results indicate that a single-amino-acid change in the CC domain of I2 (I141N) expanded its response profile to AVR3\textsubscript{EM} and increased response of the receptor to the AVR3\textsubscript{K1} isoform.

To examine whether the activity of the I2\textsuperscript{H141N} mutant protein extends to additional AVR3a variants besides AVR3\textsubscript{K1} and AVR3\textsubscript{EM}, we tested both the I2 wild type and the I2\textsuperscript{H141N} mutant for their response to selected AVR3a mutants with amino-acid substitutions at position 80 in AVR3\textsubscript{K80/I103} and AVR3\textsubscript{E80/M103} (Bos et al. 2009). I2\textsuperscript{H141N} showed expanded response to all of the mutants tested (Supplementary Fig. S4).

**I2\textsuperscript{H141N} protein accumulates at different levels compared with wild-type I2.**

To determine whether the activity of the I141N mutation on the stability of the I2 protein, we performed Western blot assays using a polyclonal antibody raised against the CC domain of R3a. We collected samples at 2, 3, and 5 dpi, because we reasoned that...
this range of time points would allow us to detect potential differences in the protein levels between I2 and I2I141N. Interestingly, at 2 and 5 dpi, wild-type I2 yielded a more intense signal than the I2I141N mutant (Fig. 6). The loss-of-response mutant protein I2I141T was used as an additional control in this experiment and only yielded a weak signal at 5 dpi (Fig. 6). Additional analysis of the remaining loss-of-response mutants at the N-terminal part of I2 showed that all of them are expressed (Supplementary Fig. S5). Of the I2 loss-of-response mutants tested, I2I141D, I2I141L, I2I141K, I2I141V, I2I141F, and I2N330E all accumulated to lower level than the wild-type I2 protein.

R3aI148N has a response profile similar to that of wild-type R3a. To investigate whether the I141N mutation in the CC domain of I2 could also alter the response profile of R3a, we introduced this mutation in R3a to generate the R3aI148N mutant. We then co-expressed R3aI148N with the AVR3a variants using agroinfiltration assays in N. benthamiana and scored for the HR. The response of R3aI148N to the two AVR3a isoforms was similar to that of wild-type R3a, because a potent HR was detected only when the protein was co-expressed with AVR3aKI (HR index approximately 3) (Supplementary Fig. S6). As previously reported (Bos et al. 2009), a weak response was
sometimes observed when the wild-type R3a protein was co-expressed with the AVR3aEM variant, a trend that was also observed for the R3a141/148N mutant (HR index < 0.2). These results further indicate that, even though the 141/148 amino-acid position in the CC domain is important for the activities of I2 and R3a, different amino-acid substitutions are necessary to expand the response spectrum of these immune receptors.

I2141N confers partial resistance to a P. infestans strain expressing AVR3aEM.

To determine the degree to which the expanded response profile of I2141N translates into a wider resistance spectrum, we performed infection assays in N. benthamiana leaves expressing I2 and I2141N with different strains of P. infestans. We expressed I2 and I2141N using A. tumefaciens-mediated transformation in leaves of 3- to 4-week-old N. benthamiana plants. Approximately 15 h after agroinfiltration, we inoculated infiltrated leaves with P. infestans zoospore suspensions. We first examined the effect of the wild-type I2 protein on P. infestans strain NL00228 homozygous for Avr3aKI (Zhu et al. 2012) or strain 88069 homozygous for Avr3aEM (van West et al. 1998). I2 expression restricted infection by P. infestans NL00228, as illustrated by smaller lesion sizes compared with those observed in leaves expressing a control construct (Fig. 7). In contrast, I2 did not impact infection by strain 88069, resulting in no significant differences in lesion sizes (Fig. 7). Remarkably, the I2141N mutant protein restricted infection by both strains of P. infestans. In more detail, the effect of I2141N on the P. infestans NL00228 strain was at a level similar to the wild-type I2 (Fig. 7). Restriction of P. infestans 88069 growth in leaves expressing I2141N was evident because smaller lesions developed compared with those developed in leaves expressing a control construct (Fig. 7; Supplementary Fig. S7). These findings suggest that the I2141N mutant has an expanded resistance profile to P. infestans relative to the I2 wild-type receptor.

I2141N responds to F. oxysporum f. sp. lycopersici stealth effectors AVR2Y > M and AVR2Y > H.

We also tested the extent to which I2141N has altered response to AVR2 effectors of F. oxysporum f. sp. lycopersici.

---

**Fig. 5.** I2141N responds to AVR3aEM while retaining the response to the AVR3aKI isoform. A, Hypersensitive response (HR) phenotypes of wild-type I2 and I2141N after co-expression with the Phytophthora infestans AVR3a variants in Nicotiana benthamiana leaves. The wild-type and mutant I2 were under transcriptional control of the Cauliflower mosaic virus 35S promoter and AVR3aKI, AVR3aEM, or a truncated version of green fluorescent protein (ΔGFP) were expressed from a Potato virus X-based vector. The picture was taken at 6 days postinfiltration (dpi). B, HR indices corresponding to the experiment described in A. Values scored at 6 dpi are plotted. Bars represent the average of 20 replicas for each combination of constructs; error bars represent standard deviation.

**Fig. 6.** The I2141N gain-of-response mutant has an altered stability compared with wild-type I2 in planta. Nicotiana benthamiana leaves were agroinfiltrated with constructs to express wild-type and mutant I2 proteins or a truncated version of green fluorescent protein (ΔGFP). Total protein extracts from leaves sampled at 2, 3, and 5 days postinfiltration (dpi) were subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis followed by immunoblotting with a polyclonal antibody raised against the CC domain of R3a (a-R3a, upper panel). A band of approximately 145 kDa corresponding to I2 was present in total extracts of the leaves infiltrated with the I2 and I2141N constructs. Ponceau S staining of Rubisco (lower panel) is shown as control of the amount of protein loaded and transferred in each lane. Sizes (in kilodaltons) are indicated on the left. I2141T is a loss-of-response I2 mutant and was included as an additional negative control in this experiment. Different boxes indicate different blots.
To achieve this, we co-expressed both I2 wild-type and I2I141N mutant proteins with the AVR2 effector variants from *F. oxysporum* f. sp. *lycopersici* using agroinfiltration in *N. benthamiana*. I2I141N responded to two of the three stealthy AVR2 variants—AVR2V > M (HR index approximately 3) and AVR2R > H (HR index approximately 1.2)—while retaining the capacity to respond to AVR2 from *F. oxysporum* f. sp. *lycopersici* race 2 (HR index approximately 2.5) (Fig. 8). These results indicate that the gain-of-response mutation identified based on one pathogen effector display also increased the response spectrum to effectors from another pathogen. Therefore, the I2I141N mutant of I2 has expanded response to effectors from oomycetes and fungi, two phylogenetically unrelated plant pathogens.

**DISCUSSION**

Tomato I2 and its potato ortholog R3a are two NLR immune receptors that have been previously described to mediate resistance to fungi and oomycetes, respectively (Armstrong et al. 2005; Bos et al. 2006; Ori et al. 1997; Simons et al. 1998; Takken and Rep 2010). We discovered that I2 weakly responds to the AVR3aKI effector from *P. infestans* and also confers resistance to a strain of this pathogen that expresses this effector (Figs. 1 and 7). By using targeted mutagenesis, we recovered a mutant in the I2 protein, I2I141N, with enhanced response to both AVR3aKI and the stealthy AVR3aEM isoform that is produced by R3a-virulent races of *P. infestans* (Fig. 5). Remarkably, I2I141N conferred partial resistance to an R3a-breaking strain of *P. infestans* that expresses AVR3aEM (Fig. 7). In addition, I2I141N showed enhanced response to two of three *F. oxysporum* f. sp. *lycopersici* AVR2 stealthy variants that evade response by the wild-type I2 (Fig. 8). These findings open up exciting perspectives for the budding field of synthetic NLR-mediated disease resistance (Farnham and Baulcombe 2006; Harris et al. 2013; Segretin et al. 2014). First, knowledge generated on one NLR receptor can be exploited to improve homologous NLR from other plant species. Second, synthetic NLR immune receptors can be engineered to confer resistance to phylogenetically divergent pathogens. Overall, these approaches can be applied to develop synthetic immune receptors that are beneficial to agriculture.

In this study, we focused on two previously identified mutations at the N terminal part of R3a (R3aI148F and R3aN336Y) and transferred them to I2 based on the high level of sequence similarity the two proteins have at this region. The I2 mutants generated resulted in a loss-of-response (I2I141F) and autoactive phenotype (I2N330Y), respectively. Our knowledge of the underlying mechanisms in the I2 and R3a systems is limited. However, we propose that previous screens (Chapman et al.

**Fig. 7.** Wild-type I2 and I2I141N confer partial resistance to strains of *Phytophthora infestans*. A, Wild-type I2 and I2 mutants were expressed in *Nicotiana benthamiana* leaves under transcriptional control of the *Cauliflower mosaic virus* 35S promoter. After approximately 15 h, the infiltrated leaves were drop inoculated with *P. infestans*-zoospore suspensions corresponding to the strains NL00228 (carrying AVR3aKI) and 88069 (carrying AVR3aEM). Pictures were taken at 6 days postinoculation (dpi). B, Total area of *P. infestans* growth was determined with Image J software (Schneider et al. 2012). Values corresponding to 6 dpi are plotted. Bars represent the average of 24 replicates for each treatment; error bars represent standard deviation. The experiment was performed four times and a representative repeat is shown. The Gateway binary vector pK7WG2 was included as negative control (empty vector [ev]). I2I141T is a loss-of-response I2 mutant and was used as an additional negative control in this experiment. Significant differences between the groups are indicated by letters and were determined in an analysis of variance (P ≤ 0.05).
have revealed amino-acid positions that are important for the activity of these NLR receptors. One possibility is that the amino acids surrounding these two positions in the CC and NB-ARC domain of I2 (141 and 330), combined with the introduced substitutions, affect protein activity by preventing interaction with downstream signaling components (I2^{141F}) or by changing the overall conformation of the protein, leading to a constitutive activated state (I2^{N330Y}).

Based on our structural modeling, position 141 of I2 is located after the structurally defined CC domain, at an interdomain region between the CC and NB-ARC regions. Therefore, it is possible that a change in this residue perturbs domain–domain interactions, affecting the function of this region and interfering with the overall performance of the protein. Previous studies have highlighted the involvement of the CC domain in pathogen perception and downstream signaling (Chen et al. 2012; Hao et al. 2013; Maekawa et al. 2011; Raieidan and Moffett 2006). Raieidan et al. (2008) have previously proposed that motifs in the CC domain, including the highly conserved EDVID, mediate interactions important for the function of the protein. However, position 141 in the I2 CC domain doesn’t appear to be close to the EDVID motif (Fig. 2A); therefore, we cannot be sure about the mechanism underlying the mutation in that position. In the same study, Raieidan et al. (2008) further suggested a model where the signaling activity of the NB domain is defined by the joint function of both the CC and LRR domains and that this regulation is recognition dependent. Therefore, it is also possible that the specific amino-acid change in the CC domain perturbs intramolecular interactions with the LRR domain, thus enhancing the signaling activity of I2.

Position 330 is located near the predicted NB pocket of I2 (Fig. 2B). This region is thought to act as a switch between the active and inactive state of NLR proteins (Tameling et al. 2006). In a previous study, Harris et al. (2013) showed that single-amino-acid mutations near the NB pocket of the potato NLR protein Rx enhanced the expanded response conferred by a single mutation in the LRR domain, resulting in resistance to Poplar mosaic virus. However, saturation mutagenesis in position 330 in I2 did not result in expanded response phenotypes. It is possible that mutations in this position affect the affinity or catalysis of the ATP/ADP nucleotide. Further analysis is required before any firm conclusions can be drawn.

Stirnweis et al. (2014) identified two positions in the NB-ARC domain of the wheat powdery mildew resistance gene Pm3 that, when mutated, enhance the ability of the protein to trigger cell death in N. benthamiana and also result in expanded resistance of the Pm3f allele in wheat. They further showed that the same mutations affected the activity of another CNL rice immune receptor, Bph14, highlighting the importance of these two amino acids in a distantly related protein (Stirnweis et al. 2014). In addition, Ashikawa et al. (2012), working on two members of the Pik locus in rice, the broad-spectrum Pikm1-TS and narrow-spectrum Pik1-KA gene, generated chimeras to identify which domains define the recognition specificity. They found that a combination of the CC-NB of Pikm1-TS and the LRR of Pik1-KA was sufficient for resistance to a blast fungus isolate virulent only to Pik1-KA. Their results suggested that one or more of the polymorphic amino acids in one or both the CC or NBS domain are responsible for the recognition specificity (Ashikawa 2012). Overall, these studies support the view that the N-terminal
part of NLR protein is implicated in the perception of the pathogen. In conclusion, although our I2G141N mutant appears to be sensitized, it may also have altered specificity. Future work aiming at identifying the mechanisms mediating the observed expanded response of the I2G141N mutant protein and also addressing whether this response translates to resistance are required.

Even though transfer to I2 of the precise mutations previously identified in R3a did not yield the desirable phenotype, they helped us focus our screens for improved I2 mutants. The I2G141N mutant identified in this study has expanded response to both AVR3a isoforms from P. infestans (Fig. 5) and also to two AVR2 variants from F. oxysporum f. sp. lycopersici race 3 (Fig. 8). However, this mutant also shows a weak HR in the absence of effectors, which suggests that it has increased activation sensitivity. Most likely, this sensitized “trigger-happy” mutant has a lower threshold for activation compared with wild-type I2 and is more easily activated by weak elicitors. This scenario is supported by the expanded response of the I2G141N to the AVR3a mutants. The altered stability of I2G141N (Fig. 6) is another indication that this mutation affects the overall conformation of the protein that could make it easier for the protein to get activated (Schornack 2006). Another possibility is that the mutated protein has an altered ATP-binding ability. In the wild-type I2 protein, both forms (ATP-bound = “on” and ADP-bound = “off”) are kept in a dynamic equilibrium and, in the absence of an elicitor I2, would predominantly be inactive. In a previous study, an autoactive version of I2 was shown to be impaired in nucleotide hydrolysis (Tameling et al. 2006). A similar mechanism was proposed for an autoactive version of the flax M NLR protein, which shows increased preference for binding ATP (Williams et al. 2011). Further biochemical tests on I2G141N are required to assess whether this mutation in the N-terminal part of I2 alters the ability of the protein to bind ATP, modifying the threshold for activation.

The pathogenicity assays showed that I2 confers resistance to a P. infestans isolate homoygous for the Avr3dKI allele (Fig. 7), suggesting that tomato lines carrying this gene may confer strain-specific resistance to P. infestans. However, the level of HR observed between I2 and AVR3aKI was relatively weak; therefore, we cannot rule out that other effectors present in this P. infestans determine the observed I2-mediated resistance. Most late blight lineages infect both potato and tomato (Goodwin et al. 1998), although some lineages primarily infect potato and are not likely to cause disease on potato plants in the field (Hu et al. 2012). In a later study, Armstrong et al. (2005) screened a selection of 45 P. infestans isolates from Canada, Mexico, the United States, Argentina, Ecuador, Denmark, The Netherlands, and Scotland and found that 40 of them were homoygous for the Avr3dEM allele, 14 carried both Avr3dKI and Avr3dEM and only 1 was homoygous for Avr3dKI. After comparing the genomes of 11 ancient P. infestans strains with 15 modern isolates, Yoshida et al. (2013) revealed that the Avr3dKI allele was dominant in ancient populations whereas both Avr3a alleles are found in modern isolates, with lineages homoygous for Avr3dEM being more common. Even though, in many P. infestans populations, the Avr3dEM allele dominates, epidemics are often caused by clonal lineages. I2-expressing tomato lines may provide some degree of resistance to epidemics caused by strains homoygous for Avr3aKI, however, these races are rare in modern P. infestans populations. Therefore, improved mutants with a broader spectrum of resistance to the dominant Avr3dEM-carrying P. infestans races are needed. The R3a+ mutants previously identified failed to provide resistance against P. infestans (Chapman et al. 2014; Segretin et al. 2014). Remarkably, the I2G141N mutant identified in this study gives partial resistance to P. infestans strains carrying either of the Avr3a variants in the transient assays used (Fig. 7). These results suggest that tomato lines carrying the I2G141N mutant could confer resistance against P. infestans.

NLR genes constitute a useful tool for generating sustainable disease-resistant crops. Traditional breeding approaches based on these genes have been used extensively in tomato (Andolfo et al. 2014). Recent transgenic strategies also allow the efficient transfer of R genes between plant species (Horvath et al. 2012; Narusaka et al. 2013; Wulff et al. 2011). However, the deployment of NLR genes through both conventional breeding and transgenic approaches is hampered by the low occurrence of R genes with the useful response specificities. In this study, we show that a synthetically generated NLR mutant protein has expanded response specificities toward two different pathogens. This approach could prove useful for designing and engineering NLR with novel activities, where mutants identified in one gene could be transferred to homologs. Similar to I2 and R3a, which share a high sequence homology, other R genes with high sequence similarity could benefit from this approach. Such examples are RPP8, RCY1, and HRT from Arabidopsis thaliana; Rx and Gpa2 from potato; and Mi-1.2 and Rpi-bb2 from tomato and S. bulbocastanum, respectively. Random mutagenesis screens like the one leading to the identification of the R3a+ mutants (Segretin et al. 2014) have been extremely useful in determining critical positions affecting the response profile of R proteins. Recently, the advent of genome editing in plants (Feng et al. 2013; Jiang et al. 2013; Li et al. 2013a; Mao et al. 2013; Miao et al. 2013; Nekrasov et al. 2013; Shan et al. 2013; Xie and Yang 2013) has opened a completely new era in the field of plant biotechnology. The application of genome editing to generate synthetic R genes with expanded response specificities could significantly broaden the perspectives for breeding crop plants with a far-ranging resistance.

MATERIALS AND METHODS

Microbial strains and growth conditions.
Agrobacterium tumefaciens strain GV3101 (Hellens et al. 2000) and Escherichia coli TOP10 (Invitrogen) were used in molecular cloning experiments and library construction. These strains were cultured as previously described (Sambrook and Russell 2001) at 28°C (for GV3101) or 37°C (for TOP10) in Luria-Bertani (LB) media supplemented with the appropriate antibiotics. DNA was electroporated into electrocompetent A. tumefaciens GV3101 or transformed by heat shock into competent E. coli TOP10 cells following standard protocols (Sambrook and Russell 2001). The following isolates were used in the P. infestans infection assays: NL00228 (Zhu et al. 2012), 88069 (van West et al. 1998), and 88069td (transgenic strain expressing the red fluorescent marker tandem-dimer RFP, known as tdTomato) (Giannakopoulou et al. 2014).
Phytophthora strains were grown on rye sucrose agar, as previously described (Kamoun et al. 1998), at 18°C in the dark.

Targeted mutagenesis of I2 and R3a.

The I2 (GenBank number KR108299) clone was used in this study. The I2 open reading frame was amplified using primers I2G_F and I2G_R (Supplementary Table S1) designed to add a 4-bp (CACG) sequence to the 5′ end of the I2 sequence, which is required for directional cloning, using the pENTR/D-TOPO cloning kit (Invitrogen). I2 clones with single-residue mutations (I2G141F and I2N330Y) were obtained by inverse polymerase chain reaction (PCR) upon the pENTR::I2 backbone with sets of primers (I141F_F, I141F_R and N330Y_F, N330Y_R) designed to introduce the desired mutations. Random mutagenesis at positions 141 and 330 in the CC and NB-ARC
domains, respectively, of I2 was performed by inverse PCR upon the pENTR::I2 backbone with sets of degenerate primers (I141-x_F, I141F_F and N330x_F, N330Y_R) designed to introduce all possible sequence combinations at these positions. The amplification products were cloned with the pENTR/ D-TOPO cloning kit following standard protocols (Xu and Li 2008). The Gateway-compatible binary vector pK7WG2 (Karimi et al. 2002) was used as destination for the mutagenized I2 sequences. The R3a1148N clone with a single-residue mutation (I148N) was obtained by GenScript Site-Directed Mutagenesis Service, as described previously (Segretin et al. 2014). The binary vector pCBNptII-vnt1.1P/T-R3a (Segretin et al. 2014) was used as template and destination for the mutagenized R3a sequence.

Sequence analyses.

Plasmid DNA from the I2 mutant clones was isolated and I2 inserts were sequenced by GATC Sequencing Service using several primers to allow full coverage. Base-calling and quality values were obtained using the Phred algorithm (Ewing, Hillier et al. 1998). Sequences were analyzed with MacVector 12.6 ( Olson 1994).

Agroinfiltration assays.

Wild-type and mutant I2 and R3a clones were coinfiltrated in N. benthamiana leaves to compare their relative response to different effector proteins. Each combination of wild-type or mutant R protein and effector protein (or negative control) was infiltrated as 16 to 20 replicates per experiment and every experiment was repeated at least three times. Briefly, 10-ml LB media cultures with antibiotics (rifampicin at 50 mg/liter, gentamicin at 20 mg/liter, and spectinomycin at 100 mg/liter [I2 and AVR2 constructs] or ampicillin at 50 mg/liter [I2 and AVR2 constructs]) were inoculated with cells resuspended in protein extraction buffer (150 mM Tris-HCl [pH 7.5], 150 mM NaCl, 10% [wt/vol] glycerol, and 10 mM EDTA) with freshly added 10 mM dithiothreitol, 2% (wt/vol) polyvinyl poly-pyrrolidone, 1% (vol/vol) protease inhibitor cocktail (Sigma-Aldrich), and 1% (vol/vol) Nonidet P-40, as previously described (Win et al. 2011). Immunoblotting was performed with a poly-clonal antibody raised against the CC domain of R3a (a-R3a).

Monitoring of HR development.

N. benthamiana agroinfiltrated leaves were examined for HR-associated autofluorescence. For the assays performed in Norwich, we used a Nikon D4 camera with a 60-mm macro lens (ISO set to 1250 or 1600) equipped with a yellow filter (Kodak Wratten number 8). UV Blak-Ray longwave (365nm) lamps B-100AP were spotlights and were moved around the subject during the exposure to give a more even illumination. For the assay performed in Argentina, a UVP LLC, SW model UVLMS-38, longwave (365 nm) lamp (Ultraviolet Products) was used and the camera contained no yellow filter. The autofluorescence under exposure to UV light is associated with accumulation of phenolic compounds (Klement et al. 1990).

Infection assays.

P. infestans strains were grown on rye sucrose agar, as described by Kamoun et al. (1998), at 18°C in the dark. Spores were harvested as previously described (Kamoun et al. 1998; Schornack et al. 2010) and diluted to 50,000 spores/ml. Drop-lets of 10 μl were placed onto the abaxial side of 4-week-old detached N. benthamiana leaves, approximately 15 h after previous infiltration with A. tumefaciens GV3101 carrying wild-type I2 or I2 mutants at a final OD600 of 0.3. Leaves were incubated for up to 7 days on wet paper towels with 100% relative humidity. The trays were kept at room temperature. Quantification of the total area of infection was carried out using Image J software (Schneider et al. 2012). Mycelial growth of P. infestans strain 88069rd was visualized using a Leica Stereomicroscope (Leica Microsystems CMS GmbH) mounted with a CCD camera under UV LED illumination and filter settings for DsRed. In this case, the lesion area was monitored using bioimage analysis software. The software plugin was designed so that it could batch process a series of TIFF microscope images based on a number of core ImageJ/FIJI libraries. The algorithm extracted the intensity plane from the TIFF images, based on which masking methods were applied to identify regions with high intensity and contrast values. Tailored feature selection functions were implemented to detect objects such as the scale (pixel to micrometer) and infection areas on every image. Finally, a two-dimensional convex hull method was applied to measure recognized infection areas and score the size or perimeter of the infection (in both pixels and micrometers).

Western blots.

Wild-type and mutant I2 and R3a proteins were transiently expressed by A. tumefaciens-mediated transformation in N. benthamiana leaves, and samples were collected at 2, 3, and 5 dpi. Protein extracts were prepared by grinding leaf samples in liquid nitrogen and extracting 1 g of tissue in 3 ml of GTEN protein extraction buffer (150 mM Tris-HCl [pH 7.5], 150 mM NaCl, 10% [wt/vol] glycerol, and 10 mM EDTA) with freshly added 10 mM dithiothreitol, 2% (wt/vol) polyvinyl poly-pyrrolidone, 1% (vol/vol) protease inhibitor cocktail (Sigma-Aldrich), and 1% (vol/vol) Nonidet P-40, as previously described (Win et al. 2011). Immunoblotting was performed with a polyclonal antibody against the CC domain of R3a (a-R3a).

I2 structure predictions.

Homology models of the individual CC and NB-ARC regions of I2 were generated using protein fold recognition algorithms, as implemented by four different servers: Infold2 (Buenavista et al. 2012; McGuffin et al. 2015), iTASSER (Zhang 2008), Phyre2 (Kelley et al. 2015), and SWISS-MODEL (Biasini et al. 2014). For the CC domain, three of the prediction programs (iTASSER, Phyre2, and SWISS-MODEL) identified the CC domain of the barley CNL protein MLA10 (PDB code 3QFL) as the top-scoring template for modeling of
the I2 CC domain. IntFOLD2 (Buena vista et al. 2012; McGuffin et al. 2015) produced a model based on the CC domain of the potato CNL protein Rx (PDB code 4M7O), which adopts a distinct structure, quite different at the three-dimensional level from MLA10. The NB-ARC domain was modeled using Apaf-1 (PDB code 1Z6T chain B) (Riedl et al. 2005) as template, which was the top score of IntFold2. That template is in agreement with previously published experimental evidence showing that I2 has ATPase activity (Tamelung et al. 2002), as determined by positioning of the key motifs known to be required for ATPases.
